Fifty two clinical samples collected from patients with postoperative wound infections in various age groups were examined for presence of multidrugs resistant bacteria pathogens in especially *Staphylococcus aureus*. The majority of samples were for age between 31 to 40 year (32.69%) followed by other age groups, while the lowest samples were taken from age group 1 to 10 year (5.76%) $P<0.05$. One hundred and thirty one isolates were identify and the main causative agents was *S. aureus* (24 isolates 18.32%), while other bacterial types isolated from postoperative wounds were as follow: *Escherichia coli* 16 (12.21%) , *Klebsiella* spp. 11 (8.39%), *Enterobacter cloaeca* 8 (6.1%), *Proteus* spp. 7 (5.34%), *Pseudomonas aeruginosa* 20 (15.26%), *Staphylococcus epidermidis* 11(8.39%), *Staphylococcus saprophyticus* 8 (6.1%), *Staphylococcus xylosus* 5 (3.81%), Viridance streptococci 10 (7.63%), *Streptococcus pyogenes* 7 (5.34%) and *Enterococcus faecalis* 4 (3.05%) $P<0.01$. Sixteen antibiotics were used to test the resistance of *S. aureus*. Penicillin G gave 100% resistance ratio for all of 24 tested isolates, while the highly affected antibiotic was cefotaxime that gave the lowest resistance percentage (16.66%), other antibiotics had ranges of resistance between these limits $P<0.01$. *S. aureus* develop a resistance mode for at least eight antibiotics. The biggest percentage of resistance was for the resistance of four antibiotics (21.18%) $P<0.01$.

Keywords: *Staphylococcus aureus* MDRSA, postoperative wound infections.

INTRODUCTION

Infectious diseases still represent an important cause of morbidity and mortality among humans, especially in developing countries. Even though pharmaceutical companies have produced a number of new antibacterial drugs in the last years, resistance to these drugs by bacteria has increased and has now become a global concern. In general, bacteria have the genetic ability to transmit and acquire resistance to drugs used as therapeutic agents (Klein et al., 2007). *Staphylococcus aureus* is recognized as one of the major causes of infections in humans occurring in both the community and the hospital. *S. aureus* is a Gram-positive, catalase positive, coagulase positive, non-motile coccus bacterium that causes a variety of human infection in all age groups (Goto et al., 2009). It is the major causative agent in surgical wound infections and epidermal skin diseases in

newborn infants (Diekema et al., 2001). *S. aureus* infection may also be superimposed on superficial dermatological diseases such as eczema, pediculosis and mycosis (Henderson, 2006). They live as commensals in anterior naves of over half the population of humans (Lee et al., 2011). The cocci are spread from these sites into the environment by the hands, and kerchief, clothing and dust. *S. aureus* is an opportunistic pathogen in the sense that it causes infection most commonly in tissues and sites with lowered host resistance such as in individuals with diabetes, old malnourished persons and other chronic cases (Ghazal et al., 2011). *S. aureus* causes folliculitis, boil, furnculosis, scalded skin syndrome, conjunctivitis, paronychia, mastitis, and toxic shock syndrome for menstruating women who use tampons. Staphylococcal

pneumonia can occur if staphylococcal infection spreads to the lungs (Mattner et al., 2010). Hospital acquired Staphylococcal infections are common in newborn babies, surgical patients and hospital staff. Patients develop sepsis in operation wounds, which take place in the theatre during operation, and others post-operations in the ward (Chamber, 2005).

S. aureus is one of the most important etiological agents of many hospital-acquired infections as well as community-acquired infections and poses a constant therapeutic problem to clinicians (Stobberingh, 2007). In recent years, a strong correlation between isolation of *S. aureus* and occurrence of nosocomial infections became a constant problem to hospitals and clinical centers. Methicillin and its derivatives became the drugs of choice for the treatment of infections caused by *S. aureus*. The appearance of multi drugs resistant *S. aureus* (MDRSA) was followed by various patterns of resistance to antibiotics (Goto et al., 2009; Dietrich et al., 2004). Each year some 500,000 patients in American hospitals contract a Staphylococcal infection (Couto et al., 2000). The role of antibiotics is, however, more controversial when the skin is only colonized and not clinically infected (Henderson, 2006; Daum and Seal, 2001). Infection rate from *S. aureus* is high. Urgent control measures should be taken to combat the renowned etiology of both nosocomial and community acquired infection. In recent years, many isolates of *S. aureus* have evolved resistance to both synthetic and traditional antimicrobial chemotherapy and their prevalence outside the hospital is of potential epidemiological threat (Ghazal et al., 2011; Diekema et al., 2001). Obviously, beneficial retrospective studies on multi-drug resistance must put the available conventional antibiotics in the area into consideration. Antibiotic resistance pattern of *S. aureus* (coagulase positive). Antibiograms of MDRSA from hospitalized patients from 17 institutions in eight countries in Asia, Pacific and South Africa have shown that, the proportion of MRSA in this region were higher (ranging from 5.0% in the Philippines to 79.5% in Hong Kong. This proportion was higher than reported in other geographic regions contributing to over the same time: Latin America (34.9%), United States (34.2%), Europe (26.3%) and Canada (5.7%) (Diekema et al., 2001; Lee et al., 2011; Frikin et al., 2003).

Prolonged hospitalization and antibiotic therapy especially with -lactam antibiotics predispose patients to the acquisition of MDRS (Grisold et al., 2002). Hospital-acquired MDRS are usually associated with increased expression of multiple antibiotic resistance genes, including those coding for aminoglycoside resistance (Kaplan et al., 2005).

The objectives of this study were to determine the main bacterial causative agents associated with post operative wound infections and the prevalence of multi drugs resistant *S. aureus* (MDRSA) infections in patient with post operative wound infections in hospitals of Basrah

governorate with study of antibiogram and antibiotics resistance pattern of *S. aureus.*

MATERIALS AND METHODS

Clinical samples

The study was undertaken in Basrah teaching and general Basrah hospitals in Basrah governorate between June and October, 2011. Fifty two clinical specimens as a swab taken from various aged patients with different locations of post operative wounds under sterile conditions.

Bacteriological technique for isolation and identification

The swab samples were collected before wound dressing. They were inoculated aseptically into sterile brain-heart infusion as transport medium and were transported to the laboratory within two hours for analysis. The samples were analyzed using the standard bacteriological media like blood agar, heated blood agar, mannitol salt agar, MacConkey agar, etc. All the bacterial isolates thus obtained were characterized and identified by studying their cultural and morphological features from the results of Gram staining reaction, serological and biochemical tests such as catalase, coagulase, motility, oxidase, indole, citrate utilization, urease, carbohydrate oxidation/fermentation etc according to the standard techniques (Forbes et al., 2002; Cowan and Steel, 2004). The main causative agents (has a highest prevalence of isolation) were tested for their susceptibility to 16 different kinds of antimicrobial agents using disk diffusion method.

Antimicrobial agents and *in vitro* susceptibility pattern

Only the conventional antibiotics available for frequent use by patients in the area were considered for this study. Commercially prepared disks (Hi Media, India) were used in this study (ampicillin, penicillin G, amoxicillin, erythromycin, tetracycline, gentamicin, Chloramphenicol, rifapicin, tobramycin, neomycin, nitrofurantoin, Ciprofloxacin, cefotaxime, Amoxycillin/Clavulanic acid, vancomycin and Methicillin).

The disc diffusion method for in-vitro antibiotic susceptibility test and the evaluation of the antimicrobial susceptibility was carried according to the guidelines of the NCCLS (2002), in comparison with standard table supplies by manufacture.

Standardization of inoculums

Four pure colonies of each isolate on a 24 h plate culture were randomly selected and inoculated into 2 ml of sterile peptone water broth in Bijou bottles. This was incubated at 37°C for 6 h and the turbidity was adjusted by serial dilution in phosphate buffer saline (pH 7. 2) to match an opacity tube containing 0. 5 ml of 1% barium chloride in 1% suplhuric acid (a Mc Farlands 0.5 barium sulphate standard containing 105 cfu/ml of the inoculums). One milliliter (1 ml) of the culture dilution (bacteria suspension) was transferred into a well dried surface of diagnostic sensitivity test agar (DST) medium and tilted to spread evenly over the entire surface of the agar plate. The excess fluid was drained off and dried in incubator for less than 15 min. antibiotic discs were then placed on the surface of the inoculated plate, placed in a refrigerator to allow proper diffusion of the antibiotics and incubated aerobically at 37°C for 18 to 24 h (over-night). *S. aureus* NCTC 6751 *Staph.epidermidis* ATCC 12228 and *E. coli* NCTC 5933 were used as control organisms for the

Table 1. Numbers of patients according to clinical source of isolation.

Postoperative wounds/ or samples site	Numbers of patients	Percentage
Abdomen	10*	19.23
Leg	6	11.53
Arm	5	9.61

sensitivity test. The diameter of the zone of inhibition was measured in millimeter. The result of each antimicrobial agent tested was reported as susceptible or resistant when the test organism was compared with the control and manufacturer's manuals for interpretation.

Multiple drugs resistant *S. aureus* resistant (MDRSA)

The percentage of the *S. aureus* that showed multiple antibiotic resistance was estimated and recorded. The percentage resistance was calculated as follows:

Percentage resistance = (No of resistant isolates/No of isolates tested with the antibiotic) × 100

Statistical analysis

The results were statistically analyzed by using ANOVA and T-test in the SPSS (Statistical Package for the Social Sciences) package (Version 17). The present study was carried out with approvment and agreement of Ethical and Medical Committee in College of Medicine –university of Basrah.

RESULTS

Fifty two clinical cases were collected from patients with post operative wounds in various sites with various

percentages as follow:

Abdomen 10 (19.23), leg 6 (11.53), arm 5 (9.61), thigh 3 (5.76), knee 4 (7.69), head 8 (15.38), neck 7 (13.75) and chest 9 (17.30). There are no significal differences between sites of postoperative wound P≥0.05 (Table 1).

Table 2 illustrates the numbers of samples in various age groups. The majority of samples were for age between 31 to 40 years (32.69%) followed by other age groups while the lowest samples were taken from age group 1 to 10 years (5.76%). There are statistically differences between age group and infection P<0.05.

In the present study, one hundred thirty one isolates were identify and confirmed diagnosed by standard techniques, these isolated were belong various genus and types as show in Table 3. The main causative agents that have a highest isolation percentages was *S. aureus* 24 isolates in percentages 18.32% , while other bacterial types isolated from postoperative wounds were as follow:

E. coli 16 (12.21%)*, Klebsiella spp* 11(8.39%), *E. cloaeca* 8 (6.1%), *Proteus spp* 7(5.34%), *P. aeruginosa* 20 (15.26%) , *S. epidermidis 11* (8.39%), *Staphylococcus saprophyticus* 8 (6.1%), *Staphylococcus xylosus* 5 (3.81%), Viridance streptococci 10 (7.63%), *Streptococcus pyogenes* 7 (*5.34*%) and *Enterococcus*

Table 3. Numbers of isolates and bacterial types isolated from patient with postoperative wounds.

faecalis 4 (3.05%).There are a highly statistically differences between numbers of isolates among various bacterial types P<0.01.

In Table 4, sixteen antibiotics were used to test the resistance of *S. aureus* against them. Penicillin G gave 100% resistance ratio in all of 24 tested isolates, while the highly affected antibiotic was cefotaxime that gave the lowest resistance percentage (16.66%), other antibiotics had ranges of resistance between these limits. There are a highly statistically differences between numbers of antibiotics resistant among *S. aureus* (P<0.01).

The most important results in this study were shown in Table 5. That clarifies the multiple resistance patterns of *S. aureus* against various numbers of antibiotics, *S. aureus* develop resistance modes for at lease eight antibiotics that could be become a big problem in treating staphylococcal infections. The biggest percentage of resistance was for resist of four antibiotics (21.18%). No resistance recorded for ten and eleven antibiotics, in addition, to show that resistance against one antibiotic has percentage of 12.5.There are a highly statistically differences between percentages of antibiotics resistant (P<0.01).

DISCUSSION

In the present study, the prevalence of multidrug resistance *S. aureus* (MDRSA) among patients with postoperative wound infections was found significantly higher. The majority of MDRSA of infection isolates found to be resistant to most of β-lactam antibiotics and resistant to more than four of non lactam antibiotics. These isolate had been designated multidrug-resistant *S. aureus* (MDRSA).

S. aureus remains the most prominent etiology of pyogenic infections. This organism was observed in 24 (8.32%) cases of postoperative wound infections. Cross implication of this organism in diverse clinical cases makes it of importance to the epidemiologists. Febrile noticed among the patients could just be explained as body's immunological reaction to infection. The trend of antibiotic resistant to large number of commonly prescribed antibiotics observed in this study confirmed the validity of earlier observation (Lowry, 1998). Despite the emergence of penicillin resistance in 1942, the antibiotic is still being used to treat myriads of Staphylococcal infection. The 100% penicillin G resistance observed in this research area might have emerged from he hospitals and spread to the community (Mattner et al., 2010). Even the improved form of penicillin, ampicillin had 83.33% resistance thus contributing the record of sick individuals worldwide with ampicillin resistant infection (Okeke et al., 1999). Resistance of 16.66% to the third generation cephalosporin, cefotaxime observed in this study can be attributed to abuse of antibiotics by illegal hospital within the study area since parenteral drugs are not easily abused by individuals. Incidentally, seven of the ten isolates that produced beta lactamase were resistant to all the ß-lactam antibiotics used in this study. This revealed that the resistance is purely plasmid based

since ß-lactamase production is plasmid based (Versalovic and Mason, 2005). This contributed a lot to the level of multiple drug resistance as about 21.18% of the isolates show resistance to at least four antibiotics. Consideration of the socio-demography of the patients revealed that the adult above 30 year dominated (32.69%). They can shift chemotherapy easily to drugs that are stable against ß-lactamase enzyme like fluoroquinolone which however cannot be used by the children in the first category (Peacock et al., 2002). Though higher MDRSA was observed in this study, the antibiotics could provide a better therapy than the beta lactam drugs used. The reason might not be far from the stability of the drug to beta lactamase production. The resistance however might suggest the role of mec A gene in the isolates (Rosenthal et al., 2010). In view of the foregoing, this would be chemotherapy of choice due to the observed low resistance of 20.83 and 24.2% to amoxicillin/clavulanic acid and vancomycin, respectively. The upsurge in the antibiotic resistance noticed in this study is in agreement with an earlier report (Shabina et al., 2008) where antibiotic abuse and high prevalence of self medication with antibiotics were identified as being responsible for the selection of antibiotic resistant bacterial strains.

Although, the sensitivity of the organism isolated to the third generation cephalosporin (cefotaxime) was generally excellent in the present study, the high cost of this group of drugs precludes their use as first choice in the treatment of postoperative wounds infections and septicemia, usage policy that would be made applicable to the different tiers of our health care providers at the primary, secondary and tertiary levels. This can be done concurrently with sustained enlightenment and media publicity focusing attention on the dangers of high incidence of bacterial resistance to antibacterial agents in general and the ultimate consequences.

The trends noticed in the present study is in accordance with the general trends noticed in other hospital settings (Shabina et al., 2008; Snyder, 2000; Umolu, 2002) and in Saudi Arabia (Akbar et al., 2000; Al-Mendalawi, 2010). It is noticed that MDRSA detected in the present study is higher than those reported previously in Saudi Arabia (Bilal and Gedebou, 2000; Bukharie, 2010). The emergence of MDRSA causes difficulties in the treatment of infections caused by *S. aureus*. Antibiotic resistant-strain is a problem for the infected patients who are responding poorly to treatment and problem to the hospital, which perform control and prevention programs. The rates of MDRSA originated from nosocomial infections Several risk factors for the acquisition of MDRSA among postoperative wound infections had been identified: Prolonged hospitalization, severe underlying illness in patients who are exposed to MDRSA in the hospital and prolonged exposure to antibiotics (Hall, 2004; Harbarth et al., 2000).

Other measures that may prevent the nosocomial transmission of MDRSA include improved antibiotic stewardship, staff cohorting, maintenance of appropriate staffing ratios, reductions in length of hospital stays, contact isolation, active microbiologic surveillance, and better staff education (Kang et al., 2005). Currently, the efficacy of many of these individual infection control interventions remains in doubt. Many studies reporting improvement in infection control outcomes (e.g. reduced

transmission, decreasing prevalence) involve simultaneous institution of several of these measures, making it impossible to tease out the effects of any of the individual components (Kummerer, 2004; Levy, 2002). High prevalence of multiple drug resistance among isolates in the present study clearly indicated the excessive or inappropriate use of antibiotics in community (Livermore, 2005; File ,1999).

In Iraq, like in many other countries, antibiotics are readily available from the pharmacy desk. Alternatively, pharmacists prescribe medications to patients just based on their external symptoms, causing the intake of wrong antibiotic and/or over or under dosage. Moreover, in majority of cases, patients do not complete the prescribed course of antibiotics. This causes patients to be at the hospital harboring resistant strains. These strains may cause endogenous or exogenous infections in other patients.

The higher prevalence of resistance to anti-microbial agents in this environment could be due to widespread, indiscriminate use of antibiotics. The formulation and implementation of a national drug policy by Iraqi governments are fundamental to ensure rational drug use. Proper use of drugs has to be promoted by providing objective information and training (Yamasaki, et al., 2003). The idea of vaccine against Staphylococcal infection would be a welcomed development since vaccines are not usually available for abuse. It is time to embrace the use of local plant extract with proven

therapeutic and prophylactic potency (Lubbe, 2003; Wenzel and Edmond, 2000).

In conclusion, the resistance rates of *S. aureus* to antimicrobial agents among hospital acquired infections isolates were found significantly higher (p<0.01). Hospital environment is a risk factor for the prevalence of MDRSA in the hospitalized patients, visitors, and hospital staff and may spread a major risk to the community. Efforts are therefore needed to reduce the spread of MDRSA by strict application of infection control guidelines.
